1.0 INTRODUCTION

The media extension to the Intel Architecture (IA) instruction set includes single-instruction, multiple-data (SIMD) instructions. This application note presents examples of code that exploit these instructions. Specifically, the median_mmx function presented here illustrates how to use some of the new MMX instructions (PSUBB, PADD, PCMPGTB), logic instructions (PAND, POR, PANDN), and a 64-bit move instruction (MOVQ) to implement a median filter. The performance improvement relative to scalar IA code for the median filter is due to the ability of MMX code to operate on eight, 8-bit values simultaneously. Also, the new conditional instructions allows the elimination of data-dependent branching which greatly reduces mispredicted branching.
2.0. MEDIAN FILTER FUNCTION

For images that have random noise, a median filter removes much of the noise without causing the blurring typical of a linear low pass filter. The median filter described in this paper takes the value of a non-edge pixel, and the eight pixels around it itself, left, right, upper left, upper center, upper right, lower left, lower center, lower right. Of these nine values, the middle (not an average) value is used for the resulting image. For the edges, the existing pixel value is used without change. Figure 1 shows how a median filter works.

![Figure 1. A Simple Example of a Median Filter](image)

<table>
<thead>

</tr>
</tbody>
</table>

From the example in Figure 1, consider the (2, 2) element. The resulting value is found by taking (9 3 4 1 3 7 2 5 9), sorting them to (1 2 3 3 4 5 7 9 9) and using the fifth element, 4.

The median filter algorithm that this paper describes does a straight copy of the edge pixel values. The interior pixel values are processed eight at a time. This example also assumes the input data is in 8-bit unsigned grayscale values. For these reasons, it is assumed that the image width is on the order of $8n + 2$. If the image width is different, it is recommended that the C code compensate, since this data would be outside the inner loop and not worth special treatment in the assembler.

When this median filter processes the interior pixel values, it uses several loops to compute the final values. Consider the pseudocode shown in Figure 2. First, it must process each row (line 1). Then, it must process each set of eight values in that row (line 2). For each set of values, the appropriate nine pixel values are loaded (line 3). Then the bubble sort begins: the bubble sort keeps count of the maximum number of items that need to be sorted (line 4), then for each of the items from 0 up to this maximum number (line 5), the eight sets of nine values get sorted and swapped (line 6).

![Figure 2. Pseudocode for Interior Pixel Processing](image)

One disadvantage of the implementation of this filter is a number of unaligned memory accesses. These were necessary to load the adjacent pixel values. This is of some concern, since an unaligned access adds three cycles of latency before the result can be used. The good news is that the unaligned memory accesses occur outside of the computationally intensive inner two loops. The net effect after the optimizations described later is that the unaligned penalty is only 1852 out of 794714 cycles.
2.1. Interior Pixels

The bulk of the work and the best opportunity to take advantage of the MMX instructions for this median filter happens when filtering interior pixel values. To get a median value, the filter must consider the current pixel value and the eight adjacent pixel values. Then it must sort them to find the median value.

Sorting is a well researched subject. Because there are only nine values to sort, a bubble sort was selected. While other sort algorithms theoretically behave better ($\text{nlogn vs n squared}$) the difficulty with more advanced sort routines is that $n$ must be much larger than nine before their additional overhead is balanced by their improved performance. The major advantage of the bubble sort is that, in conjunction with MMX instructions, eight consecutive pixel values can be computed simultaneously, as described below. Another advantage is that the nature of the median filter allows quitting from the bubble sort after finding the middle value. The bubble sort assembly code for a median value offers another advantage during the sort because the code only has to store the middle sorted value.

The first thing that must be done for each data set is to load all nine of the values that must be sorted into temporary storage. Although it would be optimal to put all nine values into registers, there are only eight MMX registers. However, having the values loaded sequentially in storage allows the programmer to use a counter as an index to access the data that is needed. Also, memory locations that are frequently used tend to be in the cache so the MMX instructions incur no extra delay. An extra step in the initialization code to align the storage address on an eight byte boundary was taken to avoid unnecessary unaligned accesses. Since the aligned values are on the stack, the code is still reentrant. The only time that unaligned accesses occur is the initial read when copying data to aligned temporary storage. This is unavoidable because the nine data points are positioned relative to the current point, so reading these values results in unaligned accesses. Despite the initial inconvenience, this is still the fastest way to execute this task.

After the nine values are loaded, the SortAndSwap begins. The SortAndSwap part of the code uses MMX registers that hold eight 8-bit values. This phase operates on two registers at a time. Figure 3 illustrates how the SortAndSwap works. First, each register is copied to another register (lines 1 and 2). Then a mask is generated by using PCMPGTB (lines 3 and 4). The mask is used by PAND to leave all the higher values in one register and all the lower values in the other register (lines 5 and 6). The mask is then copied using MOVQ because the following PANDN instructions are destructive to the mask (line 7). All the lower values are then stored in the masks by using PANDN on the original register values (lines 8 and 9). The instruction POR is then used to get all the lower values in one register and all the higher values in another register (lines 10 and 11). This results in two registers with sorted values where the smaller value bubbles down (or to the right).

Although this technique is used in this paper, it could not be used directly since the nine values from the input are unsigned data, and there is no unsigned compare instruction in the MMX instruction set. Some method of comparing unsigned data had to be devised. One way to do this would have been to use PSUBUSB on the two values being sorted as seen in Figure 4. The PSUBUSB saturates negative differences to zero. This saturation identifies which bytes have a greater or equal unsigned value in MM1 (line 2). Comparing the result of PSUBUSB (line 2) against eight bytes of zeroes using PCMPGTB (line 3) yields a mask. From there, the steps to sort and swap the data are the same as lines 5 through 11 from Figure 3.
Using MMX™ Instructions to Implement Median Filter

March 1996

Figure 3. SortAndSwap

For example, let mm0 and mm1 have the following signed values:

<table>
<thead>
<tr>
<th>mm0</th>
<th>7</th>
<th>8</th>
<th>8</th>
<th>0</th>
<th>-2</th>
<th>-3</th>
<th>-5</th>
<th>5</th>
</tr>
</thead>
<tbody>
<tr>
<td>mm1</td>
<td>8</td>
<td>8</td>
<td>0</td>
<td>-2</td>
<td>-3</td>
<td>-5</td>
<td>5</td>
<td>1</td>
</tr>
</tbody>
</table>

The core of the SortAndSwap loop:

1. MOVQ mm2, mm0 ; duplicate mm0 into mm2
2. MOVQ mm3, mm1 ; duplicate mm1 into mm3
3. MOVQ mm7, mm0 ; set mm7 up to be the mask
4. PCMPGTB mm7, mm1 ; mm7 is the mask of (mm0 > mm1)
    ; mm7:
    | 00 | 00 | FF | FF | FF | FF | 00 | FF |
5. PAND mm0, mm7 ; mm0 holds the higher values of mm0
6. PAND mm1, mm7 ; mm1 holds the lower values of mm1
    ; mm0:
    | 00 | 00 | 8 | 0 | -2 | -3 | 00 | 5 |
    ; mm1:
    | 00 | 00 | 0 | -2 | -3 | -5 | 00 | 1 |
7. MOVQ mm5, mm7 ; copy the mask to use in pand

; realistically, instructions 7 & 8 would pair, but they are being left separate to combine commands that function similarly

8. PANDN mm7, mm2 ; mm7 holds the lower values of mm0
9. PANDN mm5, mm3 ; mm5 holds the higher values of mm1
    ; mm2:
    | 7 | 8 | 00 | 00 | 00 | 00 | -5 | 00 |
    ; mm3:
    | 8 | 8 | 00 | 00 | 00 | 00 | 5 | 00 |
10. POR mm0, mm5 ; mm0 holds all the higher values
11. POR mm1, mm7 ; mm1 holds all the lower values
    ; mm0:
    | 8 | 8 | 8 | 0 | -2 | -3 | 5 | 5 |
    ; mm1:
    | 7 | 8 | 0 | -2 | -3 | -5 | -5 | 1 |

Figure 4. Using PSUBUSB to Generate a Mask On Unsigned

For example, let mm0 and mm1 have the following signed values:

<table>
<thead>
<tr>
<th>mm0</th>
<th>7</th>
<th>8</th>
<th>8</th>
<th>0</th>
<th>-2</th>
<th>-3</th>
<th>-5</th>
<th>5</th>
</tr>
</thead>
<tbody>
<tr>
<td>mm1</td>
<td>8</td>
<td>8</td>
<td>0</td>
<td>-2</td>
<td>-3</td>
<td>-5</td>
<td>5</td>
<td>1</td>
</tr>
</tbody>
</table>

To get a mask from unsigned data:

1. MOVQ mm7, mm0 ; set mm7 up to be a mask
2. PSUBUSB mm7, mm1 ; get zeros for mm0 < mm1
    ; mm7:
    | 00 | 00 | 8 | 2 | 1 | 2 | 0 | 4 |
3. PCMPGTB mm7, 0000000000000000b ; compare bytes to all zeroes
    ; mm7:
    | FF | FF | FF | FF | 00 | 00 | FF | 00 |

; mm7 now holds the mask of mm0 < mm1 which can operate on signed data

Since the subtraction in Figure 3 cannot occur until both registers of eight pixel values have data in the inner loop, this method was not chosen. Rather, the method used in this paper to give the effect of signed data operates outside of the SortAndSwap loop. While the nine values were being read, 128 was subtracted from each byte before it was written to the temporary storage that the sort uses. The subtraction changes all the byte values to signed numbers in such a way that the ordering relation between any two pixels is invariant. Hence, the entire inner loop of the sort can be done using these signed numbers. When
the sort is complete and it is time to store the median value, 128 is added back to recover the original pixel values. Because the subtraction is from a static number, the subtraction can be done while loading to temporary storage. Doing this keeps the adjustment for unsigned data out of the innermost loop. This means that this technique has fewer instructions than the technique illustrated in Figure 4, and this is why subtracting 128 was chosen. Subtracting 128 works for this example since the values are only being compared. This would not work in an example where the values needed higher math such as multiplication or division.

2.2. Edge Pixels

The simplest task of this median filter is to copy the edge pixel values. The column edges were copied as the rows were processed to take advantage of having the input and output pointers in the right place at the right time. Two methods were tried to copy the row edges. First, both row edges were copied in the same loop. This way yields just one loop to process both rows. Intuitively, one might think that the writes and reads would pair since they aren't dependent on each other. However, since each of these instructions access memory, they must all be issued in the U-pipe, and hence cannot be paired.

Second, the method was tried where the first row was copied, then the non-edge pixels were processed, and last row was copied. This way avoids having to calculate where the last row begins, and takes advantage of having the input and output pointers much in the right place. Excerpts for each method follow.

Example 1 shows the first way: copy both top and bottom rows in one loop. To copy the bottom row this way, the beginning of the last row must be calculated. This is at nCols*(nRows-1) which gets stored in eax (line 5). Note that the IMUL instruction takes 10 cycles to execute. The number of times that eight 8-bit bytes can be copied gets stored in ebx (line 6). In the loop, two reads from memory and two writes to memory occur to do both the top and bottom rows (lines 8 through 11). Just like the next example, the input and output pointers are advanced, the loop count decrements, and the loop continues until all the pertinent information has been copied (lines 12 through 15).

Example 2 shows the row pixels copied first at the top, then after the non-edge pixels have been processed, the bottom row pixels are copied. Each of these loops, like the loop in Figure 1, needs to set a
counter of how many sets of eight are in the row (lines 1 and 12). Unlike the loop in Figure 1, both of these loops do only one read from memory and only one write to memory since only one row is being copied at a time (lines 3 and 4, 14 and 15). Then, again like the loop in Figure 1, the input and output pointers are advanced, the counter decrements, and the rows are copied to completion (lines 5 through 8, 16 through 19).

Example 2. Copy Top Then Copy Bottom Rows

```
1   mov   ebx, nColSets ; ebx contains the number of sets of 8 in a row
2  CopyTop:
3   MOVQ  mm0, [ecx] ; get first row value to a register
4   MOVQ  [edx], mm0 ; copy first row value to memory
5   add   ecx, 8 ; advance the pIn pointer
6   add   edx, 8 ; advance the qOut pointer
7   dec   ebx ; count the sets of 8 columns done in a row
8   jg    CopyTop ; if more sets, keep copying by 8's
9   ;
10  ; process all of the non-edge pixels...
11  ;
12   mov   ebx, nColSets ; set ebx to the number of columns in the image
13  CopyBottom:
14  MOVQ  mm0, [ecx] ; get first row value to a register
15  MOVQ  [edx], mm0 ; copy first row value to memory
16  add   ecx, 8 ; advance the pIn pointer
17  add   edx, 8 ; advance the qOut pointer
18  dec   ebx ; count the sets of 8 columns done in a row
19  jg    _CopyBottom ; if more sets, keep copying by 8's
```

For the example used to code this median filter, it was advantageous to copy the bottom row after the inner pixels had been processed. The key instruction that was eliminated with this method was the ten cycle IMUL instruction needed to gain access to the bottom of the array. It is expected that this advantage would diminish with images of increasing width.

Another method of copying the edge rows would be to copy both the top and bottom after the inner pixel value processing. This method avoids the IMUL instruction. But, this method requires that the code track two input pointers and two output pointers, ensure that the input came from the correct area of memory, and that the output pointers write to the correct area of memory.

2.3. Further Optimizations

One optimization is to sort not just from the top down, but to sort the top half and the bottom half of the nine values at the same time, and compare the result. This will potentially allow better pairing, since the top half and the bottom half sorts have no data in common; so they would have no data dependency pipe stalls. Before we could apply this technique however, the code must be modified in the SortAndSwap sections only four registers are required (perhaps by using memory for one of the operands). Since there are nine of twenty cycles without paired instructions in this section, this would be a great exercise for the reader.

Another idea for further optimization is to unroll the SortAndSwap loop into the Load9Pixels loop. Usually for loop unrolling, the programmer needs to set one loop variable according to what was unrolled before jumping to the rest of the loop. Note that to unroll a bubble sort, two variables indicating loop
boundaries must be set instead of the typical one. These are for the declining maximum and iterations up to the maximum (here, ebx< and esi) for the bubble sort. Again, it was not done because the instructions in Load9Pixels perform well enough for this example.
3.0. PERFORMANCE

Performance for this example is measured in cycles per pixel. The C instructions used to take this measurement can be found in Appendix B. The C code took 1598 cycles per pixel. The MMX instructions used 415 cycles per pixel.
